kernels have been applied to classification problems for decades, but traditionally they were often restricted to one-dimensional data or small data sets. as machine learning grows, from simple linear regression to high-dimensional statistical learning and deep neural networks, the vast majority of research has focused on either the kernel-based methods or the various neural network variants. and it usually fits. those numbers provided the basis for the proof. for sparse activations, a hidden layer can be thought of as a collection of points in a high-dimensional vector space, and the hidden-to-output weights effectively act as a kernel function, mapping points in this high-dimensional space to points in an output space. first, they need to take appropriate care with these proofs. the input layer of a hidden-layer neural net is also called the feature map. in some contexts, a feature map is also called a kernel, and radford neal actually makes that assumption in the paper he published a few years ago. but it turns out that the proof needs a layer of hidden neurons — which turn out to be equivalent to a kernel map — and this may actually conflict with the common usage of kernel in statistics. boser, guyon and vapnik went on to develop a number of other kernel methods, extending the class of functions for which they exist. among the most notable are the support vector regression (svr) and the support vector classification (svc). svr is designed to solve complex prediction problems, such as those in medical diagnosis or financial forecasting. it uses a combination of the kernel trick and linear regression to solve the problem. for svc, they try to use the same kernel trick and only a single linear piece to predict the output. the researchers show that these kernel models not only have good generalization properties, they also have superior performance in practice to standard nonlinear regression and classification procedures.

the kernel is a filesystem driver (think "driver" as the program that makes your devices work). the user-level programs can actually do a lot with the kernel, but its really what the kernel does that is really important. the kernel deals with all input/output, network i/o, and memory allocation. the kernel also provides the low level access to the hardware components of the system. this means the processor, ram, the i/o devices (including the disk), and even the irq mechanism (exception handling) is all handled by the kernel. to help explain the overlap between the kernels and the neural networks, researchers have found it useful to start with a simpler image recognition problem. in 2000, tomaso poggio and joseph levy, then at the massachusetts institute of technology, showed how to make an algorithm that classifies an image into one of two classes by using only three image features. in other words, you can throw out your neural network and just train a kernel. and bahris and colleagues showed that these mathematical expressions, or kernels, could even be used to classify data. this is not a trivial result. in traditional machine learning, the idea that you could replace a deep neural network with a kernel—and know that the network has really been replaced—is considered an oxymoron. if $f(\mathbf{x}, \mathbf{y})$ is a kernel function ($k(\mathbf{x}, \mathbf{y})$), there is a hope that a deep neural network can learn to approximate a kernel. the intuition here is that you have just implicitly learned how to apply $k(\mathbf{x}, \mathbf{y})$, because the weights of your network are all set up to behave like $k(\mathbf{x}, \mathbf{y})$. the big question is whether the weights of the deep neural network are set up in such a way that when you train the network for a relatively long time, you can sample points $(x_i), (y_i), (z_i)$, which might be in a lower dimensional space than the original high-dimensional data set, and so that the points $(f(x_i)), (f(y_i)), (f(z_i))$ are all points in that lower dimensional space. if that is the case, then it makes sense to say that what you have learned about $k(\mathbf{x}, \mathbf{y})$ is an implicit "intrinsic" representation of the high-dimensional data set (x) . as a result, it is a good approximation to think about a kernel $k(\mathbf{x}, \mathbf{y})$ that has been learned through a deep neural network. 5ec8ef588b
